Double blind randomised controlled trial of two different breathing techniques in the management of asthma

Background: Previous studies have shown that breathing techniques reduce short acting β2 agonist use and improve quality of life (QoL) in asthma. The primary aim of this double blind study was to compare the effects of breathing exercises focusing on shallow nasal breathing with those of non-specific upper body exercises on asthma symptoms, QoL, other measures of disease control, and inhaled corticosteroid (ICS) dose. This study also assessed the effect of peak flow monitoring on outcomes in patients using breathing techniques.

Methods: After a 2 week run in period, 57 subjects were randomised to one of two breathing techniques learned from instructional videos. During the following 30 weeks subjects practised their exercises twice daily and as needed for relief of symptoms. After week 16, two successive ICS downtitration steps were attempted. The primary outcome variables were QoL score and daily symptom score at week 12.

Results: Overall there were no clinically important differences between the groups in primary or secondary outcomes at weeks 12 or 28. The QoL score remained unchanged (0.7 at baseline v 0.5 at week 28, p = 0.11 both groups combined), as did lung function and airway responsiveness. However, across both groups, reliever use decreased by 86% (p<0.0001) and ICS dose was reduced by 50% (p<0.0001; p>0.10 between groups). Peak flow monitoring did not have a detrimental effect on asthma outcomes.

Conclusion: Breathing techniques may be useful in the management of patients with mild asthma symptoms who use a reliever frequently, but there is no evidence to favour shallow nasal breathing over non-specific upper body exercises.

Breathing techniques are among the most popular complementary medicine modalities used by people with asthma. A Cochrane review concluded that breathing exercises for asthma, such as Buteyko, yoga and diaphragmatic breathing, led to decreased use of short acting β2 agonists and a trend towards improvement in quality of life, but no consistent evidence of improved disease control such as reduced requirement for anti-inflammatory medication, reduced airway hyperresponsiveness, or improved lung function. Some proponents of breathing techniques have suggested that the failure to demonstrate improvement in lung function measures such as ambulatory peak expiratory flow (PEF) was due to the deep inspirations and forced expirations required with such monitoring. Additionally, the Cochrane review highlighted the need for further studies to evaluate the impact of breathing techniques on symptom free days, physiological measurements, and airway inflammation.

This study was designed to test the hypothesis that breathing techniques aimed at reducing tidal volume and rate of breathing and encouraging the nasal route of breathing would result in greater improvement in asthma symptoms and measures of disease control, and allow a greater reduction of inhaled corticosteroid (ICS) use than non-specific upper body exercises. A secondary hypothesis was that twice daily peak flow monitoring has no detrimental effect on asthma outcomes during treatment with either form of breathing exercise.

METHODS

Subjects
The study was conducted at a respiratory research institute in Sydney and a tertiary referral hospital in Melbourne, Australia. Subjects with stable suboptimally controlled asthma were identified from a database of volunteers and from advertising in the lay press. All subjects gave informed written consent and the institutional ethics committees of Royal Prince Alfred Hospital, Camperdown and The Alfred Hospital, Melbourne approved the study. Inclusion criteria were: age 15–80 years, as-needed reliever use >4 occasions/week, use of ICS (≥200 μg/day for ≥3 months with no dose change during the previous 4 weeks), current non-smoker, forced expiratory volume in 1 second (FEV1) >50% and <90% predicted or FEV1/forced vital capacity (FVC) ratio <70%, reversibility ≥200 ml to bronchodilator within previous 6 months, and daily access to television/video player. Exclusion criteria included current smoking or >10 pack-year smoking history, recently unstable asthma, and prior tuition in Buteyko (for full details see online supplement at http://www.thoraxjn.com/supplemental).

Study design
The study was a double blind, randomised, controlled, multicentre comparison of two breathing techniques—one (group A) aimed at reducing tidal volume, reducing hyperventilation and encouraging nasal route of breathing, and the other (group B) involving non-specific upper body mobility exercises. After a 2 week run in period on pre-existing treatment, subjects were randomised (fig 1) using computer generated permuted blocks (block size of four). Subjects learned and practised their exercises by video tuition in Buteyko (for full details see online supplement at http://www.thoraxjn.com/supplemental).

Abbreviations: ACQ, Asthma Control Questionnaire; AQLQ, Asthma Quality of Life Questionnaire; FEV1, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroid; PEF, peak expiratory flow
Interventions

In the videos the duration, format, and style of presentation were matched for both groups. All subjects were provided with a detailed “Instruction” video for initial teaching and a “Daily Exercises” video. They were instructed to practise their exercises twice daily, watching the video at least once daily. The “Instruction” video could be used again at any time. An unblinded research assistant contacted the subjects at 2 weekly intervals to review the essential elements of the breathing exercises, answer questions, and clarify concerns. Subjects were also offered face to face tuition.

Outcome measurements

All measurements were made by trained research assistants who were blinded to the subjects’ treatment allocation. Baseline data were collected at week 0. At each visit, spirometry was measured and airway resistance was recorded using the forced oscillation technique. Route of breathing (primarily nasal, primarily oral, mixed) was established from headset mounted thermistor recordings, and end tidal CO₂ measurements from exhaled breath, while subjects were distracted with questionnaire tasks. Airway responsiveness to mannitol was assessed at all visits except week 0. Patient and Physician Global Assessments of Asthma Control were recorded on a visual analogue scale at all visits, and the Asthma Control Questionnaire (ACQ) and Asthma Quality of Life Questionnaire-Sydney (AQLQ) range 0–4 (best–worst quality of life) were administered at all visits except week 6.

Subjects used electronic diary spirometers (AM2, Erich Jaeger GmbH, Hoechberg, Germany) twice daily to record symptom intensity, night waking, use of reliever, Global Assessment of Asthma Control, time spent doing routine exercises, and number of times exercises were used for symptom relief. FEV₁ and PEF were obtained from the three component forced oscillation technique. Baseline data were collected at week 0. At each visit, spirometry was measured and airway resistance was recorded using the forced oscillation technique. Route of breathing (primarily nasal, primarily oral, mixed) was established from headset mounted thermistor recordings, and end tidal CO₂ measurements from exhaled breath, while subjects were distracted with questionnaire tasks. Airway responsiveness to mannitol was assessed at all visits except week 0. Patient and Physician Global Assessments of Asthma Control were recorded on a visual analogue scale at all visits, and the Asthma Control Questionnaire (ACQ) and Asthma Quality of Life Questionnaire-Sydney (AQLQ) range 0–4 (best–worst quality of life) were administered at all visits except week 6.

Changes in medications, exacerbations, and adverse events were recorded at all visits. Moderate exacerbations were defined as ≥2 consecutive days of increased reliever use by ≥2 occasions/day and/or increase in symptoms (≥1 episode of nocturnal asthma/night and/or early waking requiring reliever) over baseline, and/or in the investigator’s opinion the subject was experiencing an exacerbation. They were treated with double dose ICS for 2 weeks. Severe exacerbations were defined by requirement for oral corticosteroids.

Analysis of data

Analysis was based on intention-to-treat, with all data from both centres combined. Handling of subject withdrawals and missing data are described in the online supplement.

The primary outcome analyses were AQLQ (total) score and daily symptom score between groups at week 12 (completion of ICS maintenance phase), with adjustment for baseline. All outcome variables were compared between groups at weeks 12 and 28. Outcome variables were also

**Figure 1** Schematic of study design. Inhaled corticosteroid (ICS) dose remained constant until week 16, after which two successive dose reductions of 50% were attempted for subjects who satisfied the eligibility for reduction criteria (weeks 16 and 22). *ICS dose reduction if clinically indicated (both groups).
compared within groups at weeks 12 and 28. The impact of PEF monitoring was assessed by comparing outcome variables before and after PEF monitoring for clinic measurements (week 12 v week 14, week 28 v week 30), and with and without PEF monitoring for diary variables. Outcomes were compared using unpaired (two sample) t tests adjusted for baseline and paired t tests for normally distributed data, and by Mann-Whitney U and Wilcoxon tests for non-parametric data. Because the ACQ includes a question about reliever use, questions 1–6 (ACQ: lung function data removed) and questions 1–5 (ACQ: lung function and reliever data removed) were also analysed. The sample size of 50 subjects was calculated based on detecting a clinically meaningful difference (0.5) in AQLQ score between groups with 80% power (α = 0.05). To detect a 0.5 change in symptom score (80% power, α = 0.05), a total sample size of 80 was required.

RESULTS

Fifty seven subjects were randomised (28 to group A and 29 to group B). Nine subjects (five from group A and four from group B) withdrew before completion of the study (fig 2). Blinding of randomisation allocation was not broken for any subject. Baseline demographic and clinical characteristics are shown in table 2. At baseline, subjects had mild airway obstruction and used on average 3 puffs reliever/day. Asthma related quality of life was well preserved and was slightly better in group B at baseline (p = 0.0417). There were no significant differences in other variables.

During the study there was no significant difference between the groups in the self-reported time spent on routine daily exercises (group A: median 12 min/day (IQR 7–20); group B: 16 min/day (IQR 8–20); p = 0.66). Median overall adherence to twice daily electronic monitoring was 62%.

Primary outcome measures

Primary outcome measures are shown in table 3. At week 12 there was no significant difference between the two groups in AQLQ score (p = 0.29). There were small differences favouring group B in daytime symptom scores (p = 0.0192) and night-time symptom scores (p = 0.0636).

Secondary outcome measures (weeks 1–12)

Reliever use

Both groups had a dramatic reduction in reliever use commencing from week 1 after randomisation (fig 3), with no significant differences between the groups at week 12. The proportion of reliever-free days increased in both groups between baseline and week 12 (group A: median baseline 6.7%, week 12 53.5%, p = 0.001; group B: baseline 8.3%, week 12 55.3%, p = 0.0001) with no significant differences between groups (p = 0.49 at baseline; p = 0.19 at week 12).

Other variables

There was no significant difference between ACQ scores at week 12 (p = 0.234). However, there was a statistically significant improvement in ACQ at week 12 in group B (p = 0.0324) but not in group A (p = 0.49; see online supplement). A significant improvement in ACQ was seen for group B even when the components for β2 agonist use and lung function were omitted (see online supplement).

There were no significant differences between groups in Patient or Physician Global Assessments at week 12, although Physician Global Assessment improved significantly for group B but not group A compared with baseline (p = 0.0467 and p = 0.073, respectively).

There was no significant difference between groups in clinic FEV1 at week 12 (p = 0.30), although there was a small reduction in FEV1 (0.084 l) by week 12 in group B (p = 0.0359). There were no consistent differences between the two groups at week 12 for airway responsiveness to mannitol, or for mean airway resistance before and after deep inspiration. The airway responsiveness data need to be interpreted with caution due to missing data (see online supplement).

There was no difference between the groups at week 12 in volume of deep inspiration and number of breaths per minute (see online supplement), end tidal CO2, or route of breathing, and no significant changes in any of these measures within either group during weeks 0–12. The end tidal CO2 and route of breathing data need to be interpreted with caution due to missing data (see online supplement).

Inhaled corticosteroid dose reduction (weeks 13–28)

ICS dose

At baseline, median daily ICS dose (BDP equivalent) was 800 µg (IQR 758–1900, n = 28) and 800 µg (500–2000, n = 29) for groups A and B, respectively (p = 0.92). The final ICS dose was 200 µg (100–275, n = 23) and 187.5 µg (119–250, n = 25), respectively. The mean reduction in ICS dose for those who remained in the study beyond week 13 was 50% (IQR 50–75, p<0.0001 compared with baseline (both groups combined, n = 48).
Clinical outcomes after ICS dose reduction

At week 28 there was no significant difference between groups in AQLQ score, daytime or night time symptom scores, reliever use, symptom-free days, Patient or Physician Global Assessments, ACQ scores, FEV₁, mean airway resistance before and after deep inspiration, airway responsiveness to mannitol, or end tidal CO₂ adjusted for baseline (table 3). Data for mannitol challenge, route of breathing, and end tidal CO₂ were not available for all subjects at week 28 (see online supplement), and these results therefore need to be interpreted with caution. Of 31 subjects with route of breathing data, more subjects breathed nasally in group A than in group B. Stability of asthma was maintained in both treatment groups during reduction in ICS dosage. This was demonstrated by maintenance of, or improvement in, asthma outcomes at week 28 compared with week 12 (see online supplement).

Adverse events

Twelve moderate exacerbations were experienced by 11 subjects (three in group A and eight in group B, p = 0.11) during the study. There were 259 other adverse events (138 in group A and 121 in group B), none of which was considered to be related to treatment. Eight adverse events (five in group A and three in group B) were attributed to mannitol (see online supplement).

Potential impact of PEF monitoring on other asthma outcomes

There were no significant differences in any outcome variables between these periods, with the exception of AQLQ in group B for week 12 v week 14 (p = 0.024) where the difference favoured the post-PEF period (see online supplement).

DISCUSSION

This study found that similar improvements in asthma symptoms, reliever use, and ICS dose were achieved in subjects with mild to moderate asthma using a technique which focused on the nasal route of breathing, hypoventilation, and breath holding, and a breathing technique incorporating non-specific upper body manoeuvres.

Figure 3 Reliever use reduction.
Importantly, these changes were achieved without impacting negatively on underlying disease control, as measured by lung function and airways responsiveness. Devising a credible control for complementary medicine interventions has been acknowledged as a difficult task, and previous studies examining breathing exercises for asthma have used a variety of control arms including asthma education and relaxation, but this approach has limited the conclusions which can be drawn about the efficacy of the breathing technique itself. Instead, we used a second breathing technique for which there was no previous evidence of efficacy in a randomly selected asthma population, and in which there was no attempt to modulate pattern of breathing. Previous studies have also matched any "process" elements of the two interventions, including the instruction about symptom relief, so that the only variable was the exercises themselves. The similarity of the improvements seen in both groups, despite the widely disparate nature of the breathing exercises they were using, suggests that the observed changes were more likely to be attributable to one or more of the shared "process" elements—such as the instruction to use the exercises initially in place of reliever for symptom relief—than to the breathing exercises themselves.

Although we found significant improvements in reliever use, some patient centred outcomes and ICS dose, there were no significant changes in physiological parameters. With one exception, no previous study of breathing techniques has found an improvement in lung function or airway hyperresponsiveness, and there is no evidence that upper body exercises such as those used for group B would impact on lung function. Our results confirm no change in end tidal CO₂ as also reported by Bowler et al. While data for end tidal CO₂ and mannitol challenge in the present study should be interpreted with caution due to missing data, these findings—together with the measurement of airway resistance by the forced oscillation technique—strongly suggest that the improvements observed with both breathing techniques were not measurably related to physiological changes.

It has also been suggested that the failure of previous studies of breathing techniques to demonstrate improvements in lung function was due to a bronchoconstricting effect of deep breaths during PEF monitoring. However, we failed to find evidence that 2 week periods of PEF monitoring were detrimental, with even small improvements occurring in some measures. Our findings therefore suggest that breathing techniques do not mask any benefit or cause deterioration in other measures of asthma control.

Previous studies of breathing techniques have shown a trend towards a reduction in ICS dose. We found a significant and similar reduction in ICS dose in both groups, with no negative impact on other outcome measures. It is unlikely that this was due to improvement in airway inflammation, given the lack of change in indirect airway hyperresponsive ness. However, some of our subjects may have been relatively overtreated with ICS at entry, as many clinicians rely on markers such as reliever use to indicate whether a patient’s ICS dose is appropriate. Further, other researchers have been able to reduce ICS doses by approximately 50% in a clinical trial setting in the absence of any other intervention. Despite the lack of physiological improvement, any strategy which facilitates ICS reduction has important clinical implications and useful applications.

There are several possible mechanisms to explain the reliever reduction observed in this study. One possibility is that this effect was due to participation in a clinical trial (Hawthorne effect). However, this would be an over-simplification given that reliever reduction was substantial (86% by study end) and was sustained over 8 months. For both groups there were more symptom-free days at baseline (group A: 23.5%, group B: 22.1%) than reliever-free days (group A: 6.7%, group B: 8.3%). Similar disparities have been observed in other asthma studies, suggesting that patients may often use their reliever for prevention rather than actual relief of symptoms. Presumably, any instruction which defers or delays the taking of a β₂ agonist will minimise its habitual and pre-emptory use. Thus, while breathing exercises may not confer any particular physiological benefit, the process of using breathing techniques as first line symptom treatment may allow people to substantially reduce their use of β₂ agonist. This itself may be beneficial by reducing adrenergic side-effects, by reducing response to allergens, or by reducing mast cell tachyphylaxis.

Another possible explanation for the overall improvements is that the subjects recruited were a “special” group in terms of their personality or breathing style. No specific tests of personality, anxiety, or depression were administered. The fact that breathing exercises were mentioned in some recruitment material may have attracted subjects who were more likely to respond to the interventions, enabling both breathing techniques to function as “very active placebos”. However, the baseline clinical characteristics of the subjects from this study, including symptom and reliever frequency, were similar to those from a more conventional clinical trial recently conducted at the same centres. While it is possible that the relaxation elements of both interventions assisted in reducing anxiety and hence in reducing the perceived need for reliever, the subscores for the mood domains of the AQoL (which includes questions about anxiety) were very low in our subjects at baseline, indicating minimal impact of anxiety and—unlike in previous studies—minimal opportunity for improvement in asthma related quality of life. These subscores remained largely unchanged throughout the study, suggesting that the large reduction in β₂ agonist use was not primarily due to the relief of anxiety. There has been considerable interest in the concepts of dysfunctional breathing and hyperventilation syndrome, but the clinical importance of such conditions in people with asthma has not yet been established. The Nijmegen questionnaire has been used to assess dysfunctional breathing, but was not included in the present study as there is considerable overlap with the symptoms of asthma itself. A previous study of asthmatics with high Nijmegen scores showed improved quality of life with a breathing technique similar to our group B intervention, but there was no reduction in reliever use or ICS dose. Although some patients in the present study may have satisfied the criteria for hyperventilation, the randomisation process should have ensured that they were equally distributed between both treatment arms.

Although there was little change in AQoL score, improvements were seen in other patient centred outcome measures including Patient Global Assessment of Control and ACQ scores. These improvements suggest that the subjects’ self-efficacy was enhanced, which may have been due to a reduction in medication facilitated by breathing techniques. While the “ideal” study would include a group of control subjects who were instructed to withhold reliever without any substitute, gaining the agreement of subjects and the approval of an ethics committee would undoubtedly be difficult. In the present study, subjects in both groups were provided with a strategy that offered an alternative to reliever use which they appeared to accept as plausible and credible. We suggest that the combination of these factors enabled patients to reduce their reliever use in the absence of any other change.

In summary, this study shows that two completely different types of breathing techniques, taught by video,
can lead to a similar level of improvement in asthma outcomes particularly those relating to the use of a short acting $B_2$ agonist. These improvements are of a magnitude similar to that observed in conventional clinical trials which assess pharmacological interventions to improve asthma control, and are therefore clinically important. The improvement observed was substantial and sustained, but was not associated with a measurable effect on physiological parameters of airway inflammation. Given the magnitude of the differences in content of the two breathing techniques which were used in the present study, it appears likely that the observed clinical improvements were not due to the use of a particular type of exercise but to the process of both routine and as-required exercises that reinforce a message of relaxation and self-efficacy and provide a deferral strategy for $B_2$ agonist use. Breathing techniques may be useful in the management of patients with mild asthma symptoms who use reliever frequently, but at present there is no evidence to favour shallow breathing techniques over non-specific upper body manoeuvres.

ACKNOWLEDGEMENTS

The authors acknowledge the valuable assistance of Associate Professor Guy B Marks for additional statistical advice, Ms Karen Symons, Ms Susan Forrest-Blythe and Ms Caroline Reddel for assisting with data collection, Dr Cica Santos (unblinded medical officer), Mr Nathan Brown, Mr Phillip Munoz and Dr Cheryl Salome for assistance with the forced oscillation technique, Dr John Brannan and Dr Sandy Anderson for assistance with the manniot challenge, Mr Gunnar Ungar and Mr Tom Li for devising and constructing the CO$_2$-ROB headset, Mr Aneal Chandra for devising the analysis software for CO$_2$-ROB data, and Dr Jenny Alison for advice regarding the Group B exercises. Further details are given in the online supplement available at http://www.thoraxjnl.com/supplemental.
